Steel Catenary Riser from FPSO

Study performed at
CeSOS and MARINTEK
with Callas and Philippe
Mainçon

- Large heave motions cause large response near the seafloor
- Seeking the 20 year bending moment near the seafloor with 1 % probability of exceedance

Long-term extreme statistics

- Perform nonlinear simulations in ALL environmental conditions
Simulations must be long enough to include contributions
- Accumulate results from all simulations using their relative probability
- Straightforward, but the extent of simulations is formidable
- Concentrate nonlinear simulations to sea states where there are significant contributions
- Can the simulations lengths be reduced?

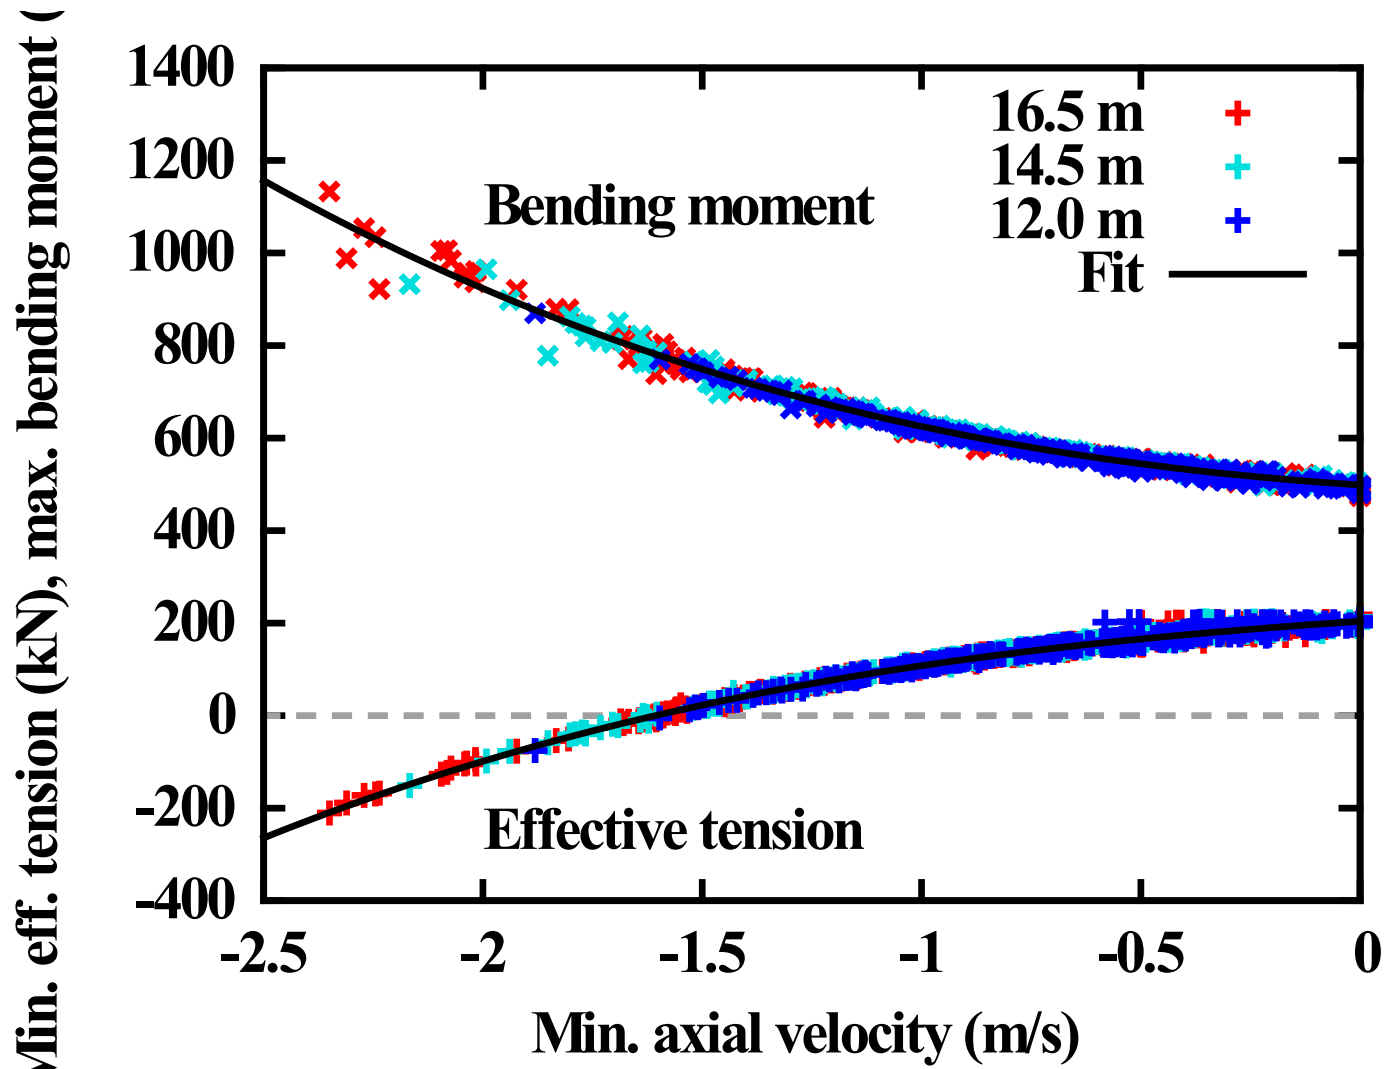

Simulation of selected intervals

1800 m water depth, 16.5 m sign wave height, 28 s intervals

Corresponding maxima

Our procedure

- **Establish a nonlinear response predictor**
- **Predict the response in all 720 sea states and find the long-term extreme response**
- **Select sea states and intervals within sea states for simulations**
- **Combine the maxima samples from the simulations to the long-term distribution at the identified response level**

Predicted long-term response from the nonlinear predictor

Long-term response from simulations (23 * 60 hours)

and from selected intervals (23 * 100 intervals)

Conclusions

- Response predictors can be used to select relevant sea states
- And relevant intervals
- Simulating selected intervals reduces simulation lengths
- And avoids extrapolation
- The method may also be used for selecting experimental conditions

Thank you!
